A ferromagnet–normal-metal–ferromagnet trilayer does not conserve spin current and as a result, the conduction electrons can create a torque on the magnetic moments. When the trilayer is connected to a superconducting electrode, the spin torque created by a current flowing perpendicularly to the trilayer can drive the system to a configuration where the two magnetic moments are perpendicular to each other. Here we argue that in contrast to the non-equilibrium torque, the equilibrium torque (or magnetic exchange interaction) does not single out the perpendicular configuration. We calculate the equilibrium torque for a one-dimensional lattice model and find that it is sensitive to the presence of the superconductivity.

1 Introduction

Spin current is a useful concept to describe the effect of the conduction electrons on the dynamics of the magnetic moments in a ferromagnet–normal-metal–ferromagnet trilayer.^{1,2,3,4} The interaction with the local exchange field causes the potential felt by the conduction electrons to be spin dependent. In the presence of a spin-dependent potential, the spin current carried by the conduction electrons is not conserved in the ferromagnetic layers. Since the total spin of the system is conserved, the missing spin current must be accounted for as a torque acting on the magnetic moments of the ferromagnets.¹ The torque from non-conservation of the equilibrium spin currents is known as the magnetic exchange (or RKKY) interaction.² (There is a direct analogy between the equilibrium spin current flowing in presence of a non zero angle between the two magnetic moments and the persistent current flowing through a mesoscopic ring in presence of an Aharonov-Bohm flux.) An additional torque is exerted out of equilibrium when a current is passed through the system. Experimentally, this non-equilibrium torque has been shown to be large enough to switch the relative orientation of the two magnetic moments of the two magnetic layers from parallel to antiparallel to each other.⁵ In this paper, we report on our investigation of these torques when the trilayer is connected to a superconducting electrode. The non-equilibrium torque has been considered in Ref. 6 where it is shown that the torque can drive the system to a configuration where the two magnetic moments are perpendicular to each other. Here, we address the question whether a similar effect can be expected for the (equilibrium) magnetic exchange interaction.

2 Definition of the spin torque

Following Ref. 6, we consider a trilayer system consisting of two ferromagnetic layers F_a and F_b with a normal metal (N) spacer and one superconducting contact (S), see Fig. 1. The magnetic moment of the layer F_b adjacent to S is considered fixed, e.g., by anisotropy forces. In a lattice formulation, the trilayer is described by the Bogoliubov-De Gennes (BdG) equation⁷

$$H_i \Psi_i + t \sum_{\langle ij \rangle} \Psi_j = \epsilon \Psi_i. \quad (1)$$

Here Ψ_i is the quasiparticle wavefunction amplitude on site $i = (i_x, i_y, i_z)$, which has an electron-hole as well as a spin index, $\Psi_i = (\psi_i^{e\uparrow}, \psi_i^{e\downarrow}, \psi_i^{h\uparrow}, \psi_i^{h\downarrow})^T$. Further, t is the hopping amplitude,

Figure 1: Schematic of the Ferromagnet–Normal-metal–Ferromagnet (FNF) trilayer under consideration. Two ferromagnetic layers, F_a and F_b , separated by a normal metal spacer (N), are connected to one normal-metal contact (left), and one superconducting contact (S, right). (A normal-metal spacer is added between F_b and S.) The arrows indicate the directions of the local exchange fields, $\vec{h}_a$ ($\theta_i = \theta$ for $i \in F_a$) and $\vec{h}_b$ ($\theta_i = 0$ for $i \in F_b$).

$\sum_{\langle ij \rangle}$ stands for the sum over nearest neighbors and,

$$H_i = \begin{pmatrix} v_i - \epsilon_F + h_i \cos \theta_i & h_i \sin \theta_i & 0 & \Delta_i \\ h_i \sin \theta_i & v_i - \epsilon_F - h_i \cos \theta_i & -\Delta_i & 0 \\ 0 & -\Delta_i^* & -v_i + \epsilon_F - h_i \cos \theta_i & -h_i \sin \theta_i \\ \Delta_i^* & 0 & -h_i \sin \theta_i & -v_i + \epsilon_F + h_i \cos \theta_i \end{pmatrix}, \quad (2)$$

where v_i is an on-site potential, ϵ_F the Fermi energy, $\vec{h}_i$ the local exchange field which we take in the xz plane, and θ_i the angle between $\vec{h}_i$ and the z axis. The superconducting gap $\Delta_i = \Delta_0$ in S and $\Delta_i = 0$ elsewhere. (This is appropriate if S is coupled to the trilayer by a point contact.)

The spin current $\vec{J}_{i_x}$ is the current associated with the time derivative of the spin density. The spin current $J_{i_x, \epsilon}$ carried by a quasi-particle at energy ϵ and with wavefunction Ψ reads

$$\vec{J}_{i_x, \epsilon} = -t \operatorname{Im} \sum_{i_y, i_z} (\psi_{i+d}^{e\dagger} \vec{\sigma} \psi_i^e - \psi_{i+d}^{hT} \vec{\sigma} \psi_i^{h*}), \quad (3)$$

with $d = (1, 0, 0)$, while the equilibrium spin current $J_{i_x}^{\text{eq}}$ is

$$\vec{J}_{i_x}^{\text{eq}} = -\frac{1}{2} \sum_{\epsilon > 0} \vec{J}_{i_x, \epsilon}. \quad (4)$$

Here, $\vec{\sigma} = (\sigma_x, \sigma_y, \sigma_z)^T$ is a vector of Pauli matrices acting on the spin index. Non-conservation of the spin current in F_a and F_b results in a torque $\vec{\tau}_a$ ($\vec{\tau}_b$) exerted on the magnetic moment of F_a (F_b) (the origin is chosen in the normal metal spacer separating F_a and F_b),

$$\vec{\tau}_a = \vec{J}_{-\infty} - \vec{J}_0, \quad \vec{\tau}_b = \vec{J}_0 - \vec{J}_{+\infty}. \quad (5)$$

3 Non-equilibrium torque

For a wide trilayer with a diffusive spacer layer, the main contribution to the non-equilibrium torque lies in the plane spanned by the two magnetic moments ($\vec{h}_a, \vec{h}_b$) (the xz plane in Fig. 1).⁶ In the absence of the superconducting contact, the non-equilibrium torque $\tau_{a(b)}^{\text{ne}}$ induced by a current I changes of sign at $\theta = 0, \pi$, thus stabilizing the configurations $\theta = 0$ or $\theta = \pi$ depending of the direction of the current.¹ The presence of the superconductor, however, gives a geometric constraint that allows one to find a relation between τ_a^{ne} and τ_b^{ne} , from which it follows that τ_a^{ne} also vanishes at $\theta = \pi/2$. To find this relation, note that the spin current vanishes inside S (for bias voltage $eV < \Delta_0$). Although the ferromagnetic layers do not conserve spin current, they do conserve the majority and minority currents parallel to their exchange fields $\vec{h}_{a(b)}$, hence

$$\vec{\tau}_a \perp \vec{h}_a, \quad \vec{\tau}_b \perp \vec{h}_b. \quad (6)$$

Since $\vec{J}_{+\infty} = 0$ and $\vec{h}_b$ points along the z -axis, we find from Eq. (6),

$$\vec{J}_0 = J_0 \vec{x} \quad (7)$$

Finally, we use that, for wide trilayers, $\vec{J}_{-\infty}$ is polarized along $\vec{h}_a$ and therefore, by Eq. (6) gives no contribution to the torque.^a The torque $\vec{\tau}_a$ is thus given by the projection of $\vec{J}_0$ to the unit vector perpendicular to $\vec{h}_a$ and hence,

$$\tau_a^{\text{ne}} = \tau_b^{\text{ne}} \cos \theta. \quad (8)$$

Equation (8) shows that the non-equilibrium torque τ_a^{ne} can stabilize the $\theta = \pi/2$ configuration. (Note, however, that the presence of the S contact creates an asymmetry between the torques τ_a and τ_b , so that it is necessary for this effect that the magnetic moment of F_b is held fixed.)

4 Equilibrium torque

The previous section dealt with the non-equilibrium torque, which lies in the plane spanned by the two magnetic moments $\vec{h}_a$ and $\vec{h}_b$. It was found that $\tau_a^{\text{ne}} = 0$ for $\theta = \pi/2$. We now ask whether the equilibrium torque has the same property.

The answer is negative. Again, we can see this by a geometrical argument. In equilibrium, no spin current flows outside the trilayer on either side, and thus $\vec{\tau}_b^{\text{eq}} = -\vec{\tau}_a^{\text{eq}} = \vec{J}_0$. In combination with Eq. (6), one then finds that $\vec{\tau}_b^{\text{eq}}$ and $\vec{\tau}_a^{\text{eq}}$ point out of the plane spanned by $\vec{h}_a$ and $\vec{h}_b$. There is no relation as simple as Eq. (8) for the out-of-plane component of the torque, hence no special behavior at $\theta = \pi/2$ is expected.

There are two ways to compute the equilibrium torque: either by a direct calculation of the equilibrium spin currents in the trilayer, cf. Eq. (4), or from the derivative of the ground state energy with respect to the angle θ ,

$$\tau_a^{\text{eq}} = \frac{\partial E}{\partial \theta}. \quad (9)$$

It should be emphasized that the equilibrium torque involves contributions from energies in the entire conduction band, as opposed to the non-equilibrium torque where only quasiparticle states near the Fermi level play a role.

To illustrate the θ dependence of τ_a^{eq} , we have performed a numerical exact diagonalization of the BdG equation (1). We have considered the special case of a one-dimensional trilayer, $i = i_x$ in Eq. (1). In Fig. 2, τ_a^{eq} is plotted as a function of θ . We notice that the equilibrium torque (exchange interaction) depends strongly on the value of the superconducting gap Δ_0 . This implies that both the direct spin exchange between the two magnets and other contributions that involve the superconductor play a role. For a very large gap $\Delta_0 \gg t$, where $2t$ is the width of the conduction band in N, the superconductor acts as a hard wall and the results are qualitatively the same as without superconductivity. However, an interesting regime appears for relatively small values of the gap $\Delta_0 < t$ where the equilibrium torque depends strongly on Δ_0 , although the actual θ -dependence of τ_a^{eq} is very sensitive to the particular choice of parameters and, for a realistic calculation, would require knowledge of the detailed band structure of the different materials. In the particular example shown in Fig. 2, for $\Delta_0 = 0.1t$ the biquadratic harmonic dominates the exchange coupling⁸, showing that, after eventual fine tuning of parameters, nontrivial values of θ can be stabilized. (A similar effect may also occur without a superconducting contact, see, e.g., Ref. 8.)

^aThis is the case if the majority and minority spins are incoherently transmitted or reflected by the ferromagnetic layers, which is a good assumption for a wide trilayer with many propagating channels at the Fermi level. However, the conclusion (8) also holds for coherent transmission or reflection Ref. 6.

Figure 2: Equilibrium torque τ^{eq} for a one-dimensional FNF trilayer with one superconducting contact. Torque is shown as a function of the angle θ between the moments of the two ferromagnetic layers, and for various values the superconducting gap Δ_0 , or without superconducting contact, see figure. The system consists of 80 sites, the relative sizes of the different layers being respectively for N, F_a , N, F_b , N and S: 9, 11, 9, 11, 4 and 36. We set $v_i = \epsilon_F = 0$ and $h_i = 0.8$. All energies are measured in units of t .
